Visuospatial working memory (WM) capacity is highly correlated with mathematical reasoning abilities and can predict future development of arithmetical performance. Activity in the intraparietal sulcus (IPS) during visuospatial WM tasks correlates with interindividual differences in WM capacity. This region has also been implicated in numerical representation, and its structure and activity reflect arithmetical performance impairments (e.g., dyscalculia). We collected behavioral ($N = 246$) and neuroimaging data ($N = 46$) in a longitudinal sample to test whether IPS activity during a visuospatial WM task could provide more information than psychological testing alone and predict arithmetical performance 2 years later in healthy participants aged 6–16 years. Nonverbal reasoning and verbal and visuospatial WM measures were found to be independent predictors of arithmetical outcome. In addition, WM activation in the left IPS predicted arithmetical outcome independently of behavioral measures. A logistic model including both behavioral and imaging data showed improved sensitivity by correctly classifying more than twice as many children as poor arithmetical performers after 2 years than a model with behavioral measures only. These results demonstrate that neuroimaging data can provide useful information in addition to behavioral assessments and be used to improve the identification of individuals at risk of future low academic performance.

Keywords: child development, fMRI, mathematics, numerical abilities, working memory

Introduction

Of the various mathematical domains taught at school, number understanding, counting, and arithmetic are those in which cognitive theory and experimental methods are the most developed (Butterworth 2005). Arithmetic is an academic skill that relies on a range of cognitive processes (Dehaene et al. 2004). Poor arithmetical abilities are a serious handicap for individuals and for society in general, increasing the risk of unemployment and depression and significantly reducing lifetime earnings (Gross 2009). Children who have difficulties in arithmetic early on tend to remain low achievers (Andersson 2010). For this reason, finding early cognitive markers of individual differences in arithmetical abilities and their future development is a critical step for the implementation of successful intervention (Ramani and Siegler 2008; Holmes et al. 2009; Räsänen et al. 2009).

Behavioral studies have suggested that working memory (WM) could be one of the cognitive markers associated with arithmetical achievement (see Raghubar et al. 2010 for review). WM refers to a set of mental processes that enable us to hold and manipulate relevant information for brief periods of time. WM capacity is correlated with arithmetical performance both in children with and without known learning difficulties (Henry and MacLean 2003; Kytälä et al. 2003; Maybery and Do 2003; Alloway et al. 2005, 2009; Geary et al. 2009; Meyer et al. 2010). WM measures can also predict future development of arithmetical ability (Jarvis and Gathercole 2003; Gersten et al. 2005; Bull et al. 2008; Alloway and Alloway 2010; but see Gathercole et al. 2003; Geary et al. 2009) above and beyond measures of general intelligence or reasoning abilities (Alloway TP and Alloway RG 2010).

A number of theoretical models of WM have been proposed, and these may differ in their potential use for the study of differences in arithmetical development (Berch 2008). Experimental studies typically make a distinction based on the type of information held in WM, whether it is verbal or visuospatial. The evidence is mixed regarding whether visuospatial or verbal WM has the most predictive value regarding the development of arithmetical abilities (Gathercole et al. 2003; Rasmussen and Bisanz 2003; Bull et al. 2008; Meyer et al. 2010) and whether WM and nonverbal reasoning have independent predictive values (Passolunghi et al. 2007; Alloway TP and Alloway RG 2010; Primi et al. 2010).

Arithmetical impairments, for example, in the case of developmental dyscalculia, may arise from deficits in elementary numerical processing such as impaired representation and processing of basic numerical magnitude, impaired numerosity coding or impaired “number sense” (see Butterworth 2005, 2010 for review). Meta-analyses have identified the intraparietal sulcus (IPS) as the locus of numerical representation (Dehaene et al. 2003; Cohen Kadosh et al. 2008). Both structure (Isaacs et al. 2001; Rotzer et al. 2008; Rykhlevskaia et al. 2009) and brain activity (Kucian et al. 2006; Price et al. 2007; Kaufmann et al. 2009; Rotzer et al. 2009; Mussolin et al. 2010) in this region reflect group differences in mathematical difficulties, and current research points to IPS abnormalities as the single biological marker of developmental dyscalculia (Rubinste, and Henik 2009; Butterworth 2010). Brain imaging data indicate that numerical and WM functions converge in the IPS (Zago and Tzourio-Mazoyer 2002; Zago et al. 2008), which shows WM activation across several stimulus presentation modalities (Linden 2007). Moreover, individual differences in activity in the IPS are correlated with WM capacity differences among adults (Todd and Marois 2005), as well as when comparing children and adults (Klingberg et al. 2002a; Crone et al. 2006).

In the present study, we first attempted to replicate previous findings regarding the predictive power of WM and reasoning measures for future arithmetical performance (Raghubar et al. 2010) using longitudinal data collected in a large sample of participants ranging in age from 6 to 16 years ($N = 246$). This focus on a wide age range is novel compared with previous
studies, which tested single age groups [Gathercole et al. 2003; Bull et al. 2008; Alloway TP and Alloway RG 2010] or used age-
corrected measures [Bull et al. 2008]. Moreover, the inclusion
of different age groups allowed us to investigate whether the
relationship between predictive measures and arithmetical
outcome changes with age. Because of the mixed evidence
regarding whether visuospatial or verbal WM is most relevant
to arithmetical abilities and of the value of recording multiple
and varied measures, we assessed 3 behavioral measures of WM,
which differed in terms of stimulus type: a verbal WM task with
word stimuli, a verbal WM task with number stimuli, and a
visuospatial WM task.

We first tested whether the different types of WM measures
and nonverbal matrix reasoning contributed to prediction of
arithmetical performance 2 years later. Arithmetical perform-
ance was assessed with grade-dependent tests of elementary
arithmetic. Our second and main goal was to assess whether
brain activity, measured as change in the blood oxygen
level-dependent (BOLD) contrast, could improve prediction
of arithmetical outcome. The hypothesis behind this analysis
was that physiological measures would provide a more direct
evaluation of the key neural substrates necessary for arithme-
tical performance. Whole-brain and local IPS activation during
a visuospatial WM task was measured in a subset of 46
participants. Bilateral IPS regions of interests (ROIs) were
defined using the results of a meta-analysis of numerical
representation [Cohen Kadosh et al. 2008], and we separately
assessed the predictive use of the left and right IPS ROIs.

Materials and Methods

Participants
Participants were healthy volunteers recruited using random sampling
from the population registry in Nynäshamn in Sweden and part of
a longitudinal study of typical development ["Brainchild" study,
Söderqvist et al. 2010]. Included here were participants aged between
6 and 16 years at the first time of testing (T1) who participated in the
second round of testing (T2) 2 years later. The upper limit of the age
range was chosen to only include participants in the educational
system at T1 and T2.

Exclusion criteria were a diagnosed neuropsychological disorder
other than attention deficit and hyperactivity disorder (ADHD) and
dyslexia, a mother tongue other than Swedish, and severe hearing
or vision impairment. We expected normal rates of these disorders in
the population. ADHD symptoms corresponding to the American Psychi-
atriy Association criteria [American Psychiatric Association, [Diagnosis
and Statistical Manual of Mental Disorders -IV], 2000] were rated by
parents for 223 of the 246 participants at T1. One child was rated as
having more than 6 symptoms of hyperactivity; none was rated as
having more than 6 symptoms of inattention. Informed consent was
obtained from the participants and from the parents of children under
18. The study was approved by the local ethics committee of the
Karolinska University Hospital, Stockholm.

Behavioral Assessment
A total of 246 participants (125 males) participated in the behavioral
assessment. The sample included participants aged 6 (N = 42), 8 (N = 37),
10 (N = 46), 12 (N = 45), 14 (N = 40), and 16 years (N = 36) at T1 (mean age:
T1, 10.83 years [SD 3.35]; T2, 12.86 [3.36]). Participants completed a large
neuropsychological battery administered individually in a quiet room.
In a separate session, arithmetical achievement was measured by a written
test performed individually in isolation or in a group.

WM Measures
Visuospatial WM was assessed using the dot matrix task from the
Automated Working Memory Assessment battery [Alloway 2007]. This
task involves remembering the location and order of dots displayed
sequentially in a grid on a computer screen. Verbal WM was assessed with a
backwards digit recall task. Numbers were read aloud to the
participants, who verbally repeated them in the reverse order. In both
of these tests, difficulty was increased after 4 trials were correctly
answered by adding one item to be remembered. The trials terminated
when 3 errors were committed on one level. The scores used were the
total number of correct trials. The third WM task was a 3-back task.
Participants were read a total of twenty Swedish words and were asked
to indicate, by responding yes or no on each trial, whether the word
was the same as the word read 3 trials before. A score was calculated by
subtracting the number of false alarms (wrong yes responses) from
the number of correct responses. Although this task has not been validated
and the data suggest poorer reliability than the other WM measures, it
was included to obtain a measure of nonnumerical verbal WM.

Reasoning Ability
Raven’s Progressive Matrices were used as a measure of reasoning ability
[Raven 1998]. Participants in the youngest age group (6-year-olds)
performed subtests A–D, while all other participants performed all
subtests (A–E), each comprising 12 items. The test did not have a time
limit, although if the participant did not give an answer within 1 min the
administrator asked for an answer.

Arithmetical Abilities
The arithmetical assessment was based on the Trends in Mathemat-
ics and Science Study [Martin et al. 2004] and Basic Number
Screening Test [Gillham and Hesse 2001] and was designed in 4
school-grade-dependent versions (grades 2, 4, 6, and 8, suitable for
14- to 27-year-olds). Grades 2 and 4 problems included magnitude
judgments, questions about the number sequence, as well as
elementary arithmetic (addition, subtraction, division, multiplication,
and fractions). Grades 6 and 8 problems included elementary
arithmetical and elementary algebra (simple equations with variables).
Items were piloted in second and sixth graders (N = 400) at 3 schools in
a suburb of Stockholm. Testing time was 30 min.

Preprocessing Analyses
The raw results of the arithmetical and reasoning tests were initially
transformed into ability scores. This transformation was carried out by
item response theory (IRT) analyses using a partial credit model. The
ability score of the IRT analyses is a measure of the probability
of a participant passing the test, a function of the difficulty level of
the item and the ability of the participant (see Bergman Nutley et al. 2010
for details). These measures were then transformed into Z-scores. This
preprocessing permitted combined analyses of different age groups,
even though the groups did not perform the exact same tasks since the
tests were age dependent.

Brain Imaging
Data Collection
A subset of 46 participants (23 males) were randomly selected to
participate in the imaging part of the study [Söderqvist et al. 2010]. This
sample included participants aged 6 (N = 6), 8 (N = 9), 10 (N = 9), 12
(N = 6), 14 (N = 9), and 16 years (N = 7) at T1 (overall mean age:
T1, 10.96 [SD 3.35]; T2, 13.02 [3.35]). Magnetic resonance imaging (MRI)
data were collected on a 1.5T Siemens scanner. T2*-weighted
functional images were acquired with a gradient-echo echo-planar
imaging (EPI) pulse sequence with repetition time = 3000 ms, echo
time = 50 ms, flip angle = 90°, 30 oblique slices, 4.5 mm slice thickness,
0.5 mm interslice distance, 220 × 220 mm field of view (FOV) and 64 ×
64 grid, resulting in a voxel size of 3.44 × 3.44 × 4.5 mm. Structural T1-
weighted spin echo images were acquired with a 3D magnetization
prepared rapid gradient echo (MPRAGE) sequence (FOV = 256 × 256
mm, 256 × 256 grid, 1 mm³ voxel size).

Functional MRI Paradigm
Participants performed a visuospatial WM grid task in two 5-min
sessions including 16 WM and 16 control trials. Trial order was
pseudorandomized. Stimuli were presented with E-Prime software
using an MRI-compatible visual system (NordicNeuroLab). Dots were presented sequentially in a 4 × 4 grid for 500 ms, with 500-ms interval between dots. Two loads (2 dots or 4 dots) were implemented in the paradigm; 1500 ms after the last dot and the grid disappeared, a cue was presented in the grid for 3000 ms. The cue was a number referring to a serial position in the previous stimulus sequence. Participants indicated with a yes/no response (right index and middle finger responses, respectively) whether the number and its position in the grid matched, for example, “2?” would prompt the participant to indicate whether the second circle had appeared in the grid position filled by the number. In the control condition, the cue (number 8) always required a “no” response. A new sequence began 2000 ms after the response cue disappeared.

Data Analysis
Preprocessing and statistical analyses (see Söderqvist et al. 2010) were carried out with SPM5 (http://www.fil.ion.ucl.ac.uk/spm/software/spm5). Separate boxcar regressors modeled correct trials of the WM and control load 2 and 4 conditions, with durations of 8 (load 2) or 10 s (load 4). These regressors were convolved with a canonical hemodynamic response function, its temporal and dispersion derivatives, and, together with regressors representing residual movement-related artifacts and the mean over scans, comprised the full model for each session. Parameter estimates calculated from the least-mean-squares fit of the model to the data were used in a pairwise contrast at the individual subject level to compare WM and control conditions, irrespective of load. Contrast images for each participant were then entered in a one-sample test group analysis. Three ROIs were defined, and mean WM-control parameter estimates were calculated for each ROI using MarsBar (Brett et al. 2002). The first ROI corresponded to the inverse function of age at T1 was the best fit for ArithmeticZ at T2 (Fig. 1). Linear, logarithmic, and inverse fits were tested, and the results indicated that an inverse fit was the best fit for ArithmeticZ at T2 (R2 = 0.580, 0.622, and 0.642, respectively). Age-1 at T1 was thus the variable entered in all subsequent regression analyses.

Multiple regression analyses were performed comparing a model with T1 Age-1 only and a model including reasoning and all 3 WM measures at T1. T2 ArithmeticZ was the dependent variable. Including the behavioral measures significantly improved the fit of the model. All 4 behavioral measures were found to be significant independent predictors of arithmetical outcome (Table 1). High reasoning and high WM scores at T1 predicted high arithmetical scores at T2.

Results
Prediction of Arithmetical Performance: Behavioral Measures
A total of 246 participants were included in the behavioral analyses. T1 behavioral measures were scores on the dot matrix, backwards digit, and 3-back WM tasks and on the Raven’s matrices reasoning task. Arithmetical performance was the dependent variable assessed at T2. Reasoning and arithmetical scores were preprocessed using IRT to take into account age group differences in items tested, obtaining individual ability scores subsequently transformed into Z-scores (see Bergman Nutley et al. 2010 for details).

In a first step, a curve-fitting analysis was performed to assess how best to model changes in arithmetical performance at T2 as a function of age at T1 (Fig. 1). Linear, logarithmic, and inverse fits were tested, and the results indicated that an inverse function of age at T1 was the best fit for ArithmeticZ at T2 (R2 = 0.580, 0.622, and 0.642, respectively). Age-1 at T1 was thus the variable entered in all subsequent regression analyses.

Multiple regression analyses were performed comparing a model with T1 Age-1 only and a model including reasoning and all 3 WM measures at T1. T2 ArithmeticZ was the dependent variable. Including the behavioral measures significantly improved the fit of the model. All 4 behavioral measures were found to be significant independent predictors of arithmetical outcome (Table 1). High reasoning and high WM scores at T1 predicted high arithmetical scores at T2.

A subset of 46 participants were scanned at T1 while performing a visuospatial WM task. The contrast of interest
compared WM conditions (loads 2 or 4) with control conditions matched for stimulus presentation and response production. WM-control mean activation was calculated in the whole-brain WM-control activation ROI and in two 8-mm-radius sphere ROIs centered in the left (−31, −54, 46) and right (37, −50, 43) IPS (coordinates from Cohen Kadosh et al. 2008; Fig. 2).

A first set of regression analyses were performed to test whether WM-control activations were significant predictors of arithmetical outcome irrespective of participants’ age. Individually, both whole-brain ROI BOLD and left IPS BOLD at T1 significantly positively predicted arithmetic performance (Table 2). Greater left IPS residual activation once the effect of age was taken into account was associated with poorer arithmetical performance 2 years later. In this case, the right IPS effect remained significant when behavioral measures were first included in the model. Results showed that in this smaller sample, behavioral measures explained 10.1% more variance than age only. Only the reasoning and visuospatial WM measures significantly contributed to the model (Table 3). Importantly, adding activation in the left IPS to the model after whole-brain activation was included led to a further significant improvement of the full regression model of 2.5% (Table 3).

**Identification of the 20% Lower Performers**

As an illustration of the added benefit of using neuroimaging data as a predictor of arithmetical outcome, we classified the

fMRI sample into the 20% lower T2 ArithmeticZ performers and 80% better performers per age group (6-, 8-, 10-, 12-, 14-, or 16-year-olds at T1). The 20% threshold was chosen as an intermediary value between the 25% poor functional numeracy observed in adults (Parsons and Bynner 2005) and the 15% cutoff used for mathematics learning disability (MLD) in elementary school children (Gairy et al. 2009). Binary logistic regression analyses were performed on these data to assess how well our models could classify the participants in these 2 categories. Sensitivity represents the proportion of lower 20% performers correctly identified as low performers and specificity the proportion of higher 80% performers correctly identified as high performers.

A model including age and all behavioral measures did not classify the participants better (trend only: $\chi^2 = 8.6, P = 0.073$, sensitivity 22.2%, specificity 97.3%, accuracy 82.6%) than a model with age alone (sensitivity 0%, specificity 100%, accuracy 80.4%). However, including whole-brain and left IPS WM-control activity made a significant improvement to the model ($\chi^2 = 6.5, P = 0.039$), with the final full model (including behavioral and BOLD measures) classifying the participants in this smaller group significantly better than the model with age alone ($\chi^2 = 15.1, P = 0.020$, sensitivity 55.6%, specificity 94.6%, accuracy 87.0%). Adding fMRI measures to the model led to the correct classification of 5 of 9 low performers instead of 2 of 9 when using the behavioral measures only.

### Discussion

This longitudinal study combined behavioral and brain imaging measures to test whether functional imaging data could improve prediction of arithmetical outcome in 6- to 16-year-old participants. Our results show that greater activation in the left IPS activity is still a significant, particular visuospatial WM, for the early identification of children at risk of poor academic outcome. WM and reasoning abilities were found to be significant predictors of arithmetical outcome. Here, reasoning and all 3 WM measures were unique predictors of arithmetical performance 2 years later, accounting together for an additional 13% of variance when age was first entered in the model. These results fit with previous findings of unique contributing effects of WM and nonverbal IQ (Alloway TP and Alloway RG 2010) and verbal and visuospatial WM (Bull et al. 2008) for the prediction of mathematical outcome and extend the findings to a wide developmental age range. Overall, there was little evidence for a change with age in the relationship between the behavioral predictors and arithmetical outcome. Our findings thus suggest a consistent association between WM and reasoning measures and arithmetical abilities throughout childhood and adolescence.

In the smaller fMRI sample, only reasoning and visuospatial WM were significant predictors of arithmetical score at T2, which suggests verbal WM may be less strongly associated with arithmetical performance. In line with these results, verbal WM measures at age 4 have been found to predict reading comprehension, writing, and spelling, but not mathematics, 2.5 years later (Gathercole et al. 2003) and to predict mathematical performance at the entrance but not at the end of the first or third years of primary school (Bull et al. 2008; see also Meyer et al. 2010). Note that, possibly counterintuitively, those verbal WM measures that were less strongly associated with arithmetical performance 2 years later in our sample, the backwards digit and 3-back tasks, were those that involved some aspect of numerical representation. Indeed, it could be argued that although the 3-back task required maintaining and updating nonnumerical Swedish words in WM, participants needed to count until 3 to perform the task accurately.

These results overall support the use of WM measures, in particular visuospatial WM, for the early identification of children at risk of poor academic outcome in arithmetic. WM training programs (Klingberg 2010) have been shown to improve clinical symptoms of psychiatric disorders such as ADHD (Klingberg et al. 2002b, 2005), as well as performance on tests of mathematics, with mathematical reasoning.

improvements observed 6 months after WM training (Holmes et al. 2009). Previous mathematics training studies have focused on specific number-related training and obtained mixed results: Training using number- versus color-based board games led to improvements in performance of a range of numerical tasks at the end of training and 9 weeks later (Ramani and Siegler 2008), while training on computerized tasks emphasizing either numerical comparison or small exact numerosities showed improvement in number comparison but not counting or arithmetic after the training and 3 weeks later (Räsänen et al. 2009).

The main aim of the current study was to investigate whether brain-imaging measures of WM would complement typical behavioral assessments and contribute uniquely to the prediction of arithmetical outcome. The analyses focused on the IPS, a brain region that has been specifically implicated in both numerical processing (Dehaene et al. 2003; Cohen Kadosh et al. 2008) and visuospatial WM (Linden 2007) and where visuospatial WM and arithmetical tasks show overlapping activity (Zago and Tzourio-Mazoyer 2002; Zago et al. 2008).

IPS activation during number processing tasks correlates with arithmetical or mathematical abilities (Rubinsteen and Henik 2009; Butterworth 2010), and IPS activation during visuospatial WM tasks correlates with WM capacity (Klingberg et al. 2002a; Todd and Marois 2005; Crone et al. 2006). However, there is no previous evidence that WM activation in the IPS may be directly linked to arithmetical performance. Instead, different neural populations may underlie the activations observed in visuospatial WM and number processing tasks. The present study argues against this by showing that neural activity during visuospatial WM tasks in the IPS has predictive value for the development of arithmetical abilities.

Our results first indicated that greater activation in the whole-brain WM-control network, in the left IPS or in the right IPS (although at trend level only), predicted better arithmetical performance 2 years later. These results are broadly consistent with those of Rotzer et al. (2009), which showed that poor arithmetical abilities were associated with weaker right IPS activation during a spatial WM task in 8- to 10-year-old children. When the age of the participants was included in our analyses, the results showed that in combination with whole-brain activity, left IPS activity during a visuospatial WM task predicted 5% more variance in arithmetical performance 2 years later than age alone. There was no significant interaction between the BOLD predictors and age, suggesting the observed effects were consistent across the age range of the participants. Further, whole-brain activity and left IPS activity predicted 2.5% more variance than age and the behavioral reasoning and WM measures. Interestingly, in the full regression models, the only significant predictors were Age%1, visuospatial WM, and left IPS activity during the visuospatial WM task, highlighting the specifically high association between visuospatial WM and arithmetical performance.

When age was taken into account as a predictor, greater activation in the left IPS was thus associated with poorer arithmetical performance 2 years later, while there was a trend for greater activation in the whole-brain ROI to be associated with better arithmetical outcome. This direction of the IPS association, and its hemispheric localization, differs from the findings of Rotzer et al. (2009). However, in their study, age was not taken into account. It is possible that age effects on the WM activation in the right IPS might have affected the observed positive correlation between right IPS WM activation and arithmetical performance observed by Rotzer et al. (2009). The direction of the left IPS residual effect observed in the current study is novel and will need to be investigated further. It is possible that a complex pattern of relative activation levels in the different brain regions of the WM network is what is relevant for predicting arithmetical outcome. Such a pattern may be behind the present finding that when age is covaried, weaker left IPS activation, in the context of a greater whole-brain network WM activation, is associated with better arithmetical outcome.

A potential limitation of these results lies in the fact that the visuospatial WM task in the scanner included the presentation of a single digit number in the response phase of the task. It is thus possible that the association between IPS activation during the task and arithmetical performance 2 years later partly reflects the processing of numerical representation in the response phase. Indeed, both spoken and written numerals have been shown to specifically activate the IPS (Naccache and Dehaene 2001; Eger et al. 2003). However, the control condition of the visuospatial WM task also included the presentation of a single digit number, which should have reduced this potential confound, and suggests that the findings observed here may be specific to visuospatial WM activation.

To test a potential application of these results, we performed additional analyses that showed that age and behavioral measures could correctly classify only 2 of 9 of the 20% lower arithmetical performers, while adding fMRI WM data to the model improved this classification more than 2-fold to 5 of 9. Although the sample sizes were small, these results suggest that fMRI data can be used to improve the identification of individuals at risk of future low academic performance in the domain of mathematics. This study thus extends previous research showing that brain measures (event-related potentials) could identify infants and young children at risk for dyslexia (Maurer et al. 2009; Gutterm et al. 2010; see Gabrieli 2009 for review) and provides further support for the usefulness of neuroimaging data. It remains to be seen which fMRI cognitive task would best predict arithmetical outcome. A combination of brain activation during a numerical processing task and numerical performance measures outside the scanner may have the best predictive power. However, an advantage of WM tasks is that they do not require number knowledge and could thus be performed, and trained, at an earlier age.

Underlying the link between visuospatial WM and arithmetical abilities may be their reliance on a common spatial “memory map.” In nonhuman primates, visuospatial information is assumed to be kept in WM by sustained activity in neurons coding specifically for stimuli at different visual angles (Funahashi et al. 1989). In humans, neural specificity for the visuospatial location of stimuli can be demonstrated by showing retinotopic organization in a cortical region. Retinotopy has been found both in the IPS and in the frontal eye field during the delay period of a visuospatial WM task (Konken and Kastner 2008; Silver and Kastner 2009). Such a spatial memory map could also be used for an analog spatial representation of numbers, and there is indeed evidence of spatial aspects of the representation of numbers. Behavioral data suggest that number comparison is performed using a mental number line, an analog spatial representation in which numerical magnitude is represented along an axis oriented according to the direction of writing (Dehaene et al. 1993). This representation enhances responses to number stimuli whose values accord with the
spatial position of the response (spatial and numerical association of response codes task; Dehaene et al. 1993) and induces corresponding left/right shifts of attention (Nicholls et al. 2008). There is evidence in early development for a number–space mapping (de Hevia and Spelke 2010) and a general magnitude representation shared between the dimensions of space, number, and time (Lourenco and Longo 2010). In adults, a common frontoparietal network supporting processing of these 3 dimensions has been proposed (Walsh 2003) and is supported by studies showing that all 3 dimensions are similarly affected by saccadic compression (Burr et al. 2010). Thus, the spatial mapping required by visuospatial WM tasks and the mental number line mapping required by number comparison and arithmetical tasks may recruit similar neural populations.

Although the effects were small, the fact that neuroimaging data could significantly improve arithmetical outcome prediction compared with behavioral measures may be related to the intermediate phenotypes concept put forwards in the imaging genetics literature (Meyer-Lindenberg and Weinberger 2006). The suggestion is that neuroimaging measures may be more sensitive to individual differences by being closer to the biological substrate. Dyscalculia and poor performance in arithmetic are quite specifically associated with dysfunction of the IPS. Imaging data, which contrasts well-matched conditions in terms of visual stimuli and motor responses, can provide information on a subpart of the components that add to a behavioral WM score, for example, processes of maintenance of information over a delay, and can provide localized measures of corresponding brain function. In addition, imaging data may reflect physiological or neural properties that might provide information about future capacity, for example, number of neurons, or measures of structural maturity (synaptic connectivity strength and myelination), which are the basis of future cognitive development. In the present study, IPS activation during visuospatial WM may thus reflect the potential of local neural resources for supporting future arithmetical development.

Note that, although our participants were overall typically developing, it is likely that our results have validity for children with larger arithmetical deficits or dyscalculia as it has been suggested that the genetic components of MLD are likely to be the same as those underlying individual differences in mathematics achievement (Kovas et al. 2007). Moreover, the results obtained here in a large age range suggest that some behavioral and brain measures are good predictors of future arithmetical performance throughout development. Further work may identify whether some measures may be more specific to young age groups, for the development of tests permitting the early identification of children at risk of poor arithmetical outcome.
